Abstract

Silver wires have become a novel bonding material in recent years. But users & field engineers are still divided over the issue of reliability performance including failure mechanism and intermetallic compounds (IMCs) formation. In this study, new type of high purity silver wire with 96Ag-3Pd-1Au alloy (96% Ag) is introduced, and the bonding properties on Al bond pad are evaluated through bondability & reliability test. Reliability tests for wire characterization are high-temperature-storage lifetime test (HTST) and unbiased highly-accelerated stress test (uHAST) with temperature and humidity. Two types of mold compounds are used which have different Cl- ion content. Below 10 ppm of Cl- ion for the green compound and 27 ppm for the normal one. Bondability, IMC formation (Ag\textsubscript{2}Al, Ag\textsubscript{3}Al) & growth rate are measured for both HTST 150\textdegree C & 175\textdegree C for 2000h and the possible failure mechanism is defined based on the micro-structural characterization from uHAST in which the repetitive oxidation and reduction reactions occur due to the galvanic reaction and the Cl- ions with sufficient moisture and thermal energy, and the reduction reaction of Ag-Al IMCs and Al pad causes to form the micro-crack failure.

Introduction

Wire bonding is the most common and traditional interconnection method for IC packages [1-3]. Although gold wire has many advantages in terms of its workability and stable chemical properties, identifying a low cost bonding material to reduce packaging costs is currently a pressing issue and highlighted activity [4]. In this aspect, from the perspective of its better workability, lower risk of bond pad metal cracking, and similar electrical conductivity and properties to gold wire, silver wire has attracted higher attention of late as a lower cost solution than Cu wire [5-10]. And also, technologies of Pd coating and the doping on Ag bonding wire have been introduced, which improve the efficiency of the fabrication process and the Ag-Al bond reliability [5, 6].

In the initial development stage of Ag-rich wire, 88% (88Ag-8Au-3Pd) Ag bonding wire had been introduced which could improve the properties of the Ag-Al bond reliability [7-10]. Regarding the phases of the Ag-Al IMCs, Ag\textsubscript{2}Al, Ag\textsubscript{3}Al, Ag\textsubscript{5}Al, Ag\textsubscript{9}Al\textsubscript{3} have been reported to have been formed, including the phases via first-principles methods [12-16]. Previously, Guo et al. [17] have reported that Ag\textsubscript{2}Al\textsubscript{5}, (Au,Ag)\textsubscript{4}Al, and Ag\textsubscript{2}Al are formed in the Au-Ag alloy-Al bond. Kai et al. [18] and Cheng et al. [19] have proposed that Ag\textsubscript{4}Al, Ag\textsubscript{3}Al and Ag\textsubscript{2}Al are formed at the bonding interface in the Ag-Au-Pd alloy-Al bond.

However, the considerable amount of Au addition in the Ag bonding wire may still increase the resistivity and hardness as well as wire cost. Therefore, silver wire market needs advanced type of Ag wire more similar to Au wire properties in terms of wire softness for die to die bonding and a low resistivity for IC / memory device of high power / frequency technology trend. It becomes a promotion of the advent of high silver content wire. The 96% Ag wire (96Ag-1Au-3Pd) has been introduced & confirmed to have good properties akin to 2N gold wire and cost reduction effect as well due to high silver and low gold alloy design. Further evaluation of 96% Ag wire is needed for bondability & reliability. Hence, the present study is carried out to investigate IMC formation and growth between 96% Ag wire and Al pad metallization under thermal reliability conditions and to define the failure mechanisms through the micro-structural characterization.

Experimental

The device has 1.3\textmu m-thick Al pads for this experiment. The package structure is as shown in Figure 1.

Figure 1. Test package structure

(Au,Ag)\textsubscript{4}Al, and Ag\textsubscript{2}Al are formed in the Au-Ag alloy-Al bond. (Au,Ag)\textsubscript{4}Al, and Ag\textsubscript{2}Al are formed in the Au-Ag alloy-Al bond. Kai et al. [18] and Cheng et al. [19] have proposed that Ag\textsubscript{4}Al, Ag\textsubscript{3}Al and Ag\textsubscript{2}Al are formed at the bonding interface in the Ag-Au-Pd alloy-Al bond.

0.7mil (17.8um), 96% Ag bonding wires (AgULTRA, Heraeus Oriental HiTec) were bonded on the thin Al pads and molded using Green and Normal EMCs. The concentration of Cl- ion was below 10 ppm for the Green and was 27 ppm for the Normal EMCs. For the Ag-Al bonding process, an automated bonding machine equipped with a capillary was
utilized. The process was conducted to determine the optimum bonding parameters. In the long term reliability test, HTST was carried out at 150°C and 175°C for 0 to 2,000 h. All the specimens were protected from the oxidizing atmosphere by N₂ gas in oven chambers at 175°C during HTST. And uHAST was also carried out at 130°C for 0 and 192 h in 85%RH using the uHAST chamber.

To determine the bondability between the Al pad and the Ag wire, a bond pull test (BPT) and ball shear test (BST) were conducted using a testing machine. And, to evaluate the morphological change and the growth rate of the Ag-Al IMCs during the reliability test, the evolution of IMCs at the bonding interface was observed using optical microscopy (OM) and scanning electron microscopy (SEM).

The specimen was mechanically polished and then ion-polished for fine polishing. To identify the phases in the Ag-Al IMCs and the failure mechanism, SEM analysis was conducted with energy-dispersive X-ray spectroscopy (EDS) and particularly by transmission electron microscopy (TEM).

Results

1. Bondability of Ag-Al bond during HTST

The bond pull strength and the ball shear strength during the HTSTs at 150°C and 175°C are shown in Figure 2 that data of 150°C is higher than that of 175°C because of different IMC growth rate. It means IMC growth rate is higher at 175°C than at 150°C and there is close relationship between Reliability performance and IMC growth rate. Therefore, thermal aging properties at 150°C during HTSTs showed much greater stability than those at 175°C.

Also the ball lifts and low test values during BPT and BST occurred after 1,000 h at 150 °C and after 240 h at 175 °C and they could have different appearance in case of molded units, while gold wire had stable values of BPT and BST until 1000 h at both 150°C and 175°C. Impurities of PCB and moisture in atmosphere might cause the degradation of Ag-Al bonds.

2. IMC structure comparison between Au-Al and Ag-Al bond

The sequence of intermetallic phase transformation per aging time under HTST 175°C for both Au-Al and Ag-Al bonds is shown in Figure 3. These are from cross-section of the molded units per aging time.

After HTST at 175 °C for 48 h, the IMC was grown the Ag bonding wire and Al pad by the atomic inter-diffusion of Ag and Al atoms.
On the other hand, Figure 5 shows FE-SEM images of the interface of the Ag-Al bonds. The Ag$_3$Al IMC region is represented by point #2 and Ag$_2$Al IMC is indicated by point #3 to 6.

**Figure 5.** IMC phases of Ag-Al bond at HTST 1,500h

### 3. Comparison of IMC growth rate using 2 types of mold compound in the Ag-Al bond

Figure 6 is shown the sequential cross-sectional OM and SEM images of the interface at molded Ag-Al bonds after HTSTs at 150°C and 175°C for 0 to 2,000 hours with the Green and Normal EMCs. No morphological differences in the IMCs growth with Green and Normal EMCs are noted in this figure. The effect of temperature on the thickness of IMCs was clearly observed, such that the thickness of IMCs became much greater as the temperature increased.

![Figure 6.](image)

**Figure 6.** Sequential cross-sectional images for 0 to 2,000 hours in HTSTs at 150°C and 175°C

![Figure 7.](image)

**Figure 7.** Growth of IMC thickness as a function of aging time in Green and Normal EMCs molded Ag-Al bonds.
Figure 7 shows the measured thickness values for the Ag-Al bonds in Green and Normal EMCs during HTST at 150°C and 175°C. These figures suggest that the growth rate, D (cm²/s), follows the equations shown below [11]:

\[ x = (D_t)^{1/2} \]

\[ D = D_0 \exp \left( -\frac{\Delta Q}{R T} \right) \]

\[ \ln D = \left( -\frac{\Delta Q}{R} \right) \left( \frac{1}{T} \right) + \ln D_0 \]

where \( T \) is the aging temperature (K), \( x \) is the IMC thickness (um), \( t \) is the aging time (s), \( R \) is gas constant, \( \Delta Q \) represents activation energy for IMC formation (kcal/mol). The growth rate constants (D) for each condition were calculated from Figure 7 and are summarized in Table 1.

### Table 1. Growth rate constants of IMC, in Green and Normal EMC molded Ag-Al bonds during HTST at 150 and 175 °C.

4. Failure mechanism in Ag-Al bond during uHAST

Figure 8 shows the cross-sectional FE-SEM image of molded Ag-Al bond after uHAST 192 hours with Green EMC. The unit was not failed at the electrical test but the critical micro-cracks and voids were observed, which were gradually evolved in the IMC layers of both Ag₂Al and Ag₃Al with the uHAST aging time.

Figure 9 showed the concentration of Cl- ions at the joint region of the wire, pad and EMC in a non-functional bond failing during uHAST for 192 h. The EDS elemental maps suggest that Al(OH)₂Cl tended to form on the Al pad as a result of corrosion [20, 21].

The Cl- ions were therefore able to initiate the corrosion and accelerate the repetitive reduction and oxidation reaction which is strongly related to the failure mechanism in the Ag-Al wire bond.

As shown in Figures 10, TEM analysis confirmed the micro-crack between Ag bonded ball and IMC layers. It could become a crack initiation point even though it was not from electrically failed unit, that is, the unit could be failed if further uHAST aging time went by. The dissolution of IMCs and the formation of Ag and Al₂O₃ due to moisture and thermal energy during uHAST could also make H₂ gas, which could cause a crack when out-gassing. The moisture control is therefore extremely important for better bonding reliability in the Ag-Al bond.
Conclusions

We studied intermetallic compound growth and failure mechanisms to determine long term reliability of 96% silver wire bonding. To determine the IMC microstructure and failure mechanism in silver wire bonding, we analyzed the problems and found the major defect points. Summarized consideration and recommendations to discover the silver wire bonding mechanism are given below.

i) Thermal aging properties at 150°C during HTSTs showed much greater stability than those at 175°C. And more stable IMC growth was shown at Ag-Al bonds than Au-Al bonds.

ii) Influences of the mold effect on the growth rate and morphologies of the Ag/Al IMC were marginal. The type of EMC did not affect the evolution of IMCs. The IMC growth rate is about 4.46 x 10^{-15} at 150°C and 2.05 x 10^{-14} at 175°C.

iii) In HTST, micro-cracks were practically observed in the IMC after HTST, but other defects were not shown.

iv) The failure mechanism can be inferred under uHAST condition from this study. Cl- ion and moisture may cause oxidation and corrosion and finally form Al_2O_3 of insulating layer, H_2 gas for crack and HCl for repetitive and accelerated reactions.

\[
\text{Ag}_2\text{Al or Ag_3Al} + \text{H}_2\text{O} \rightarrow \text{Al}_2\text{O}_3 + \text{Ag} + \text{H}_2 \\
\text{Ag}_2\text{Al or Ag_3Al} + \text{Cl}^- + \text{H}_2\text{O} \rightarrow \text{Al}_2\text{O}_3 + \text{Ag} + \text{HCl}
\]
